Abstract. The growth rate of vetiver grass [Vetiveria zizanioides (L.) Nash (Gramineae: Poaceae)], roots, and oil distribution were evaluated in an 8-month field study. The amount of vetiver oil present in the root system increased with each sampling date. In December, the final sampling period, mean root weight increased 520% from the previous sampling period (October). At the end of the study, root growth measured over 2 m long and 25 cm wide and weighed 0.48 kg (dry weight). In addition, a laboratory study was conducted to determine if the roots of vetiver grass when used as mulch, are effective against Formosan subterranean termites, Coptotermes formosanus Shiraki (Isoptera: Rhinotermitidae). In past studies, chemical components in the roots of this grass were shown to be effective repellents and toxicants to Formosan subterranean termites. In the present study, the 25% vetiver root mulch treatment proved to decrease tunneling activity and wood consumption and increase termite mortality. These results provide preliminary evidence that vetiver roots may have use as an additive to garden mulches against termites.

Vetiver grass, Vetiveria zizanioides (L.) Nash (Gramineae: Poaceae), is native to India and possesses an extensive root system beneficial in soil and water conservation where erosion is problematic (Chomchalow, 2001; National Research Council, 1993). The fast growing root system of this plant contains essential oils, natural compounds found in many different plants (Zhu et al., 2001b). Presently, vetiver grass is grown in-ground and because of the extensive root growth, it is extremely difficult to harvest efficiently.

Plants produce many natural compounds that are repellent or act to alter feeding behavior, growth, and development of insects (Duke, 1990). Chemical components of vetiver root are also very important because they possess fungicidal, herbicidal, and insecticidal properties. For example, vetiver oil and one of its minor constituents, nootkatone, have been shown to inhibit germination and seed expansion in a variety of economically important weed species (Mao et al., 2004) and possess repellent properties useful against ants, cockroaches, bedbugs, head lice, flies, and moths (Henderson et al., 2005a; National Research Council, 1993). Vetiver oil and some of its constituents are also repellent and toxic to termites (Henderson et al., 2005b; Ibrahim et al., 2004; Zhu et al., 2001a, 2001b).

Termites are ecologically important insects that aid in the breakdown of cellulose material and recycling of nutrients. For homeowners, this important role in nature is overshadowed when termites invade economically important wooden structures such as homes, buildings, and utility poles. In the United States, the most economically important termite is the Formosan subterranean termite, Coptotermes formosanus Shiraki (Isoptera: Rhinotermitidae) (Gold et al., 1999).

Presently, control of subterranean termites depends mainly on the incorporation of synthetic chemical treatments with a long persistence into the soil. There has been an increased public awareness of pesticide use in the urban landscape and an increased desire to reduce their use and implement more environmentally safe control strategies (Forschler and Jenkins, 2000). There is an increasing interest in using natural products in pest control because of their low mammalian toxicity and environmental safety (Duke, 1990). Of interest to homeowners in Louisiana is to use vetiver grass plants or roots from the plant incorporated into mulch for use around the perimeter of a structure as a repellent to termites.

While using vetiver grass roots as mulch against termites as an alternative to insecticides has been a topic of great interest (Chomchalow, 2003), research in this area is lacking. Roots of vetiver plants have been used in many areas of the world as a repellent to a variety of insects (Chomchalow, 2003; National Research Council, 1993). While most of this evidence is anecdotal, it is still useful. Over a century ago, Louisiana strawberry farmers reported that when vetiver grass roots were used as mulch on their crops, the attack of pest insects to this fruit crop were reduced to zero (Chomchalow, 2003; Greenfield, 2002). Dried vetiver grass roots have been used since the early 1900’s as sachets to protect stored clothing from mold, mildew, moths, and other insect pests (Greenfield, 2002).

The first objective was to evaluate the root growth of vetiver grass and to determine the relative amount of vetiver oil present in the roots obtained on different sampling dates. The second objective of this study was to determine if the field-grown vetiver grass roots, when used as mulch, act as a repellent and/or toxicant to termites in a laboratory setting.

Materials and Methods

Evaluation of vetiver grass root growth

Material preparation. Four vetiver grass plants (about 3 years old) were obtained from Donald O. Heumann Greenhouse and Laboratory (Poydras, La.) to be grown above ground using a modified method from previous work (http://www.vetiver.com/VNN_Root%20system.pdf). Five sections of polyvinyl chloride (PVC) sewer pipe standing 2.44 m tall and 25.40 cm in diameter (Pipeline Jet Stream Inc., Siloam Springs, Ark.) were used to hold the sand in which the vetiver grass was planted. A 3.18-cm-diameter opening was drilled 0.61 m from the top of the PVC
pipe with three additional openings drilled in a straight line every 0.31 m thereafter (Fig. 1). These openings were used to obtain sand samples. Three to five additional openings were drilled in a straight line 0.46 m directly below the last sample opening drilled, for water drainage purposes. This drilling procedure was repeated at 90°, 180°, and 270° from the initial line of openings.

Site preparation. Five holes were dug in the ground in a straight line 2.29 m apart, each at a width of 0.30 m and a depth of 0.61 m, in St. Gabriel, La. One PVC pipe was placed inside each hole, with the drilled drainage holes going in the ground (Fig. 1). To stabilize each PVC pipe and to allow water drainage, about 0.014 m³ of gray stone marble (Green Leaf Products, Haines City, Fla.) was placed in the hole around the outside of the PVC pipe. Each PVC pipe was filled with sand (AJL Enterprises, St. Gabriel, La.) until level with the top. Each sample opening was covered with duct tape to keep sand from falling out and consecutively numbered 1 to 4, beginning with the sample opening closest to the top of the PVC pipe, to indicate sampling heights (Fig. 1).

On 16 Apr. 2004, 7 d after setting up the PVC pipes, four were randomly chosen and vetiver grass was planted at an approximate depth of 0.5 m, leaving a 2.54-cm space at the top of each PVC pipe to prevent overflow when watering. One tablespoon of Miracle-Gro all purpose plant food (Scotts Miracle-Gro Co., Marysville, Ohio) was added to each setup at the beginning of the study and again at about 5 months after the vetiver grass was planted. All setups were watered daily with about 3.8 to 7.6 L of water.

Sand sampling. To analyze roots for the presence of vetiver oil, every 2 months for 8 months, sand samples were obtained using a Bayco chrome plated heavy duty soil probe (54.34 × 2.22 cm, Lawrence, Kan.). The duct tape covering was removed and samples were taken from each setup through holes at all 4 sampling heights at the 270° openings. This directional aspect was randomly selected. The soil probe was inserted through the entire width of the PVC pipe, turned slightly, and then removed. About 25.4 × 2.06 cm of sand was extracted and placed in autoclaved 250 ml I-Chem jars (7.3 × 8.6 cm; Fisher Scientific, Pittsburgh, Pa.). The soil probe was rinsed with 100% ethyl alcohol after taking each sample. Only one sample, taken from sampling height 1, was obtained from the control setup for each of the sampling dates. Duct tape was replaced after samples were obtained.

Sample Preparation. Samples were dried for 48 hours in individual polyethylene weighing dishes (140 × 140 × 25 mm; FisherBrand, Fisher Scientific) under a fume hood. Dried samples were returned to their respective I-Chem jar and 100 ml of 100% ethyl alcohol was added. Each sample was stirred vigorously for 2 min and filtered into individual, autoclaved 100 mL Pyrex laboratory bottles (Fisher Scientific) using qualitative filter paper (18.5 cm, Grade 413; VWR Scientific Products, West Chester, Pa.). Once all liquid was filtered, roots on the filter paper were removed and placed back in the original I-Chem jar. Filtered liquid samples were placed inside a refrigerator.

I-Chem jars containing remaining sand and roots were allowed to dry uncovered under a fume hood for 48 h at which point all vetiver roots were removed from the sand, weighed and recorded.

Ethyl alcohol evaporation. Filtered liquid samples were concentrated in a 50°C water bath with a rotary evaporation system (Brinkmann/Büchi Rotovapor RE120; Fisher Scientific). Once the ethyl alcohol was completely evaporated, about 1 to 3 mL of 100% ethyl alcohol was added and transferred to a 15 × 45-mm glass vial (Fisher Scientific). The samples were then dried under vacuum and stored in a freezer set at about 0°C.

Thin-layer chromatography (TLC). One hundred microliters of 100% ethyl alcohol were added to each vial and placed on a Vortex Genie 2 shaker (FisherBrand, Fisher Scientific, Pittsburg, Pennsylvania) for 10 seconds. Using a 5 µL micropipette pipet (Kimble Glassware, Vineland, N.J.), 1 µL was removed from each sample and spotted on a 10 × 20 cm silica gel TLC plate (Uniplate, Analtech Inc., Newark, Del.). All samples from their respective sampling dates were placed on 1 TLC plate. For comparison purposes, 1 µL of vetiver oil (Haitian vetiver oil; The Good Scents Company, Oak Creek, Wis.) was spotted as a standard.

TLC plates were placed inside a glass chamber containing a shallow pool of chloroform so that only the bottoms of the plates were in the liquid. The chamber was covered with a stainless steel lid and left undisturbed until the chloroform was approximately 1 cm from the top of the TLC plate. Once removed from the developing chamber the TLC plates were allowed to dry under a fume hood for 5 minutes, sprayed lightly with 50% sulfuric acid, and placed inside an oven at 120°C for 10 minutes. TLC plates were scanned with an Epson 2400 photo scanner (Epson Photo 2400; Epson America, Long Beach, Calif.) to fix the images.

Evaluation of vetiver oil quantity. Samples taken at each sampling date were visually evaluated based on the darkness of the spot on the TLC plate using the following scale: 4, very dark; 3, moderate darkness; 2, light; and 1, very light to no spot present. Darker samples indicated that a larger concentration of vetiver oil was present.

Observation of total root growth. The study was terminated 8 months after planting the vetiver grass and one PVC pipe containing a vetiver grass plant was dismantled to observe root growth. The roots were washed using a water hose to remove sand and debris and were allowed to dry under a fume hood. Once dry, the total root length and weight was recorded.

Statistical analysis. An ANOVA for repeated measures (PROC MIXED, SAS Institute 1989) was also performed for each sampling date to determine the relationship between 1) sampling height and root weight, 2) root weight and vetiver oil quantity, and 3) sampling height and vetiver oil quantity.

Vetiver grass root as mulch against termites
Vetiver root mulch preparation. One of the four vetiver grass plants planted on 16 Apr. 2004, as described above, was harvested on 7 June 2005. The roots were rinsed thoroughly with water to remove sand and debris and dried under a fume hood for 5 d. Dried roots were cut with scissors into small pieces (about 1.0 cm) and stored in covered plastic containers (18.89 × 13.81 × 9.53 cm³; Pioneer Packaging Co., North Dixon, Ky.) under a fume hood for 2 d.

Experimental containers. Three-compartment plastic containers (18 × 8 × 4 cm³ each chamber; Pioneer Packaging Co.) with small openings (3.5 × 0.3 cm²) at the bottom of the two inner walls connecting the chambers were used for this experiment. The three chambers were labeled as the nest chamber, where termites were added, treatment chamber (middle chamber), and the food chamber. Untreated balsa wood, Ochroma lagopus Swartz (5.1 × 1.4 × 0.1 cm³), was dried under a fume hood for 24 h, weighed, and placed inside the food chamber of all containers. Forty grams of autoclaved fine commercial grade construction sand (Louisiana Cement Products, Greenwell Springs, La.) was moistened with 5 ml of deionized water. Vetiver root mulch was mixed with the sand in the treatment chamber of each container. Four treatments were tested: control (no vetiver root mulch), 5%, 10%, and 25% vetiver root mulch to sand (wt:wt). Vetiver root mulch for 5%, 10%, and 25% treatments were moistened with 2, 4, and 10 mL of deionized water, respectively. Ninety worker and ten soldier Formosan subterranean termites from a colony collected in New Orleans, La., on 14 May 2005, were introduced into the nest chambers. To reach the food source, termites had to tunnel through the treatment chamber. Five replicates were performed for each treatment. Each container was covered and placed in a dark incubator at 28°C for 16 d.

Tunneling response, consumption, and mortality. On days 4, 8, 12, and 16 the bottom of each container was scanned (Epson Photo 2400; Epson America, Long Beach, Calif.) to fix the images. Images were printed to actual size to measure total tunnel length. Also, at this time, 5 mL of deionized water was added to the sand in all of the treatment chambers to maintain high moisture. On day 16, all containers were dismantled, the number of live termites was counted to determine mortality, and wood slices were cleaned, dried under a fume hood for 24 h, and weighed to determine consumption. Percent mortality was calculated using the formula: [(100 – number of live termites)/100] × 100. Percent consumption of wood slices was calculated using the formula: [(Initial wood weight – final wood weight)/Initial wood weight] × 100.

Statistical analysis. The length of tunneling for each observation date, percent consumption
of the wood samples, and percent mortality were analyzed using an analysis of variance (ANOVA) procedure (PROC GLM, SAS Institute 1989). The means were separated using Tukey’s studentized range (HSD) test. Although tunnel length for day 4 and percent consumption +1 were transformed to log to promote normality for data analysis, untransformed means are reported.

**Results**

*Evaluation of vetiver grass root growth.* Mean root weights from the fourth sampling date (December) were significantly higher than all other sampling dates with a mean weight of 0.862 g \((F = 391.22; \text{df} = 3, 9; \text{P} < 0.0001)\) (Table 1), indicating a 520% increase from the previous sampling period. There was no difference in mean root weight with respect to sampling heights \((F = 0.93; \text{df} = 3, 9; \text{P} = 0.47)\) (Table 2).

Comparison of all TLC plates with the vetiver oil standard TLC plate indicated the presence of oil in the vetiver root samples. The amount of vetiver oil present in the roots increased with each sampling date, as evidenced by darker spots on the TLC plate (Fig. 2).

There was a significant decrease in the amount of vetiver oil present in the roots with distance for the second sampling date (August: \(P < 0.0001\)). Mean root weight decreased significantly with distance at the second sampling date (August: \(P < 0.0001\)). As mean root weight increased the amount of vetiver oil increased for the second and third sampling date (August: \(P = 0.0007\), October: \(P < 0.0001\), respectively).

**Fig. 2.** TLC plate for (a) first sampling date (June), (b) second sampling date (August), (c) third sampling date (October), and (d) fourth sampling date (December). The first line for each plant are the samples taken from sampling height 1, the second line for each plant are those taken from sampling height 2, continuing to the last (fourth) sample for each plant being the sample taken at the lowest sampling height (sampling height 4).

all five replications of 25% vetiver root mulch, termites did not tunnel all the way through the treatment chamber to get to the food chamber. Instead of displaying the normal exploratory behavior, on days 8, 12, and 16, termites in the nest and treatment chambers of all vetiver root mulch treatments were very sluggish and remained clumped together. Consumption of wood was significantly lower in vetiver root mulch treatments of 10% and 25% (P = 0.001) (Table 4). The highest wood consumption was recorded in control and 5% vetiver root mulch treatments, which were not significantly different from each other. Termites in treatments consisting of 10% and 25% vetiver root mulch exhibited significantly higher mortality rates (P = 0.002) than termites present in controls (Table 4).

### Discussion

In the field study, as mean root weight increased there was an increase in the amount of vetiver oil present in the roots. It is also important to note that as vetiver plants age, the amount of vetiver oil in the root system also increases (Chomchalow, 2001).

Vetiver grass root as mulch against termites. The total length of tunnels by Formosan subterranean termites in 5%, 10%, and 25% treatments was not significantly different from the control at day 4 and day 8 (P > 0.05) (Table 3). On days 12 and 16, tunneling length was significantly less only in the 25% vetiver root mulch treatments when compared to the controls (P = 0.04 or 0.03, respectively) (Table 3). In two replications of 5% vetiver root mulch, four replications of 10% vetiver root mulch, and five replications of 25% vetiver root mulch, termites did not tunnel all the way through the treatment chamber to get to the food chamber. Instead of displaying the normal exploratory behavior, on days 8, 12, and 16, termites in the nest and treatment chambers of all vetiver root mulch treatments were very sluggish and remained clumped together. Consumption of wood was significantly lower in vetiver root mulch treatments of 10% and 25% (P = 0.001). The highest wood consumption was recorded in control and 5% vetiver root mulch treatments, which were not significantly different from each other. Termites in treatments consisting of 10% and 25% vetiver root mulch exhibited significantly higher mortality rates (P = 0.002) than termites present in controls (Table 4).

*Since the study began on 16 Apr., no previous data existed on root growth for the 16 June collection.
around the perimeter of a structure or vetiver grass roots as mulch would provide a zone of repellency against this structural pest. Results of the 25% vetiver root mulch treatments are similar to results of previous evaluations of decreased tunneling, decreased food consumption, and increased mortality of termites (with and without direct contact to treatments) in wood or sand treated with vetiver oil or its constituents (Ibrahim et al., 2004; Maistrello et al., 2000, 2001, 2002; Nix et al., 2003; Zhu et al., 2001a, 2001b).

In four replications of the 10% vetiver root mulch and all five replications of the 25% vetiver root mulch treatments, no consumption was present on the untreated pieces of wood present in the food chamber. While the mean percent wood consumption in the 25% vetiver root mulch treatment indicated a slight amount of consumption, the difference was due to the fluctuation in relative humidity. A previous wood treatment study indicated that wood treated with vetiver oil or nootkatone was not only toxic but acted as feeding deterrents and arresting agents (Maistrello et al., 2001). The unusual behavior exhibited by termites in the presence of vetiver root mulch observed on days 8, 12, and 16, is described as lingering behavior (Maistrello et al., 2002). In our laboratory evaluation, the highest tested vetiver root mulch to sand ratio proved to decrease tunneling activity and wood consumption and increase termite mortality. These results provide evidence that vetiver grass roots may be useful as a repellent to termites in urban landscapes.
