Abstract. In the olive *Olea europaea* (L.), the polyamides (PAs), putrescine, spermidine, and spermine, when added exogenously at a concentration of 1 mM in the in vitro rooting medium, combined with 5 μM auxin concentration, promoted early rooting and increased the final rooting percentage and the number of roots per explant. The effect was less evident in olive explants rooted with the basal blanching method; thin-layer chromatography of total endogenous PAs in these explants revealed lower levels on day 2 compared with controls, while by day 5 PA concentrations in both had fallen to similar levels. Furthermore, putrescine decreased the pH of the medium by 0.5 units around the explants. PAs had little effect on apple *Malus pumila* (Mill.) and no effect on almond *Prunus dulcis* (Miller) D.A. Webb and pistachio *Pistacia vera* (L.). There were also some positive effects observed, but only in olive, when rooting was induced by *Agrobacterium rhizogenes* in auxin-free medium. Few plantlets showed agropine-positive roots.

Root formation from microcuttings is a problem in fruit tree and rootstock propagation in vitro. Root induction is often inefficient, unreproducible, and generally time-consuming, particularly in almond (Rugini, 1986a) and olive (Rugini, 1986b). Proper use of growth regulators, suitable environmental conditions and, more recently, the use of *A. rhizogenes* as "root inducers" (James, 1987; Patena et al., 1987; Rugini, 1986a, 1986b) have contributed to the improvement of protocols aimed at achieving acceptable root production in micropropagated explants in some recalcitrant woody species. The transfer of the *rol B* gene of *A. rhizogenes*, which increases rooting efficiency even in woody plants, as shown by Rugini et al. (1991) in kiwi [*Actinidia deliciosa* (A. Chev.) C.F. Liang et R. Ferguson var. *delicosa*] could be of value for difficult-to-root species if transformation efficiency and regeneration capacity of tissues could be increased. However, the promotion of early rooting and increased rooting efficiency remain objectives that still have to be tackled in several woody species.

PAs have been shown to delay senescence by inhibiting ethylene biosynthesis (Altman et al., 1977; Apelbaum et al., 1981; Smith 1982) and to increase cell division (Bagni et al., 1981). In addition, after auxin treatment, the polyamine content of mung beans [*Vigna radiata* (L.)] has been found to increase considerably before root emergence, and this increase has been shown to be essential for root initiation (Friedman et al., 1985). However, exogenous treatment did not increase rooting percentage in mung bean (Jarvis et al., 1983) or in cherry (*Prunus avium* L.) (Biondi et al., 1990). Since putrescine has given positive results in preliminary experiments with early root induction in olive (Rugini and Wang, 1986), the effects of PAs on the rooting of almond, apple, and pistachio shoots as well as on some olive cultivars were studied. Further, the total endogenous PA content was also determined in explants during the first 5 days of rooting.

Received for publication 28 Mar. 1991. Accepted for publication 28 Oct. 1991. Materials and Methods

Experimental plant tissue included olive shoots of cultivars Moraiolo and Dolce Agogia, which have characteristically variable rooting efficiency, apple (*Malus pumila* Mill.) of unknown genotype, Fascionello almond, a gamma-ray mutation, and pistachio seedlings. Olive shoots had been maintained for 4 years in vitro (with subculturing every 35 to 40 days) in OM (olive basal medium, plus 18 μM zeatin riboside, 3% sucrose, and 0.7% agar) (Rugini, 1986b). Apple shoots also had been maintained in culture for 4 years on Linsmaier and Skoog (1965) medium with 4.4 μM BAP and 0.5 μM IBA, according to James and Thurbon (1979). Pistachio and almond had been maintained in culture for 2 years (with subcultures at 30 and 21 days, respectively) on Murashige and Skoog (1962) (MS) medium plus 1.5 μM BAP, 0.05 μM NAA, 3% sucrose, and 0.8% agar (Rugini, 1986a). All cultures were maintained under a 16-h photoperiod at 40 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ provided by cool-white fluorescent lamps at $24 \pm 1\text{C}$. Half-strength MS salts and vitamins supplemented with 2% sucrose, 0.8% w/v Difco Bactoagar and either 0.5 or 5 μM NAA, at pH 5.5 were used as a rooting medium. All media were autoclave for 15 min at 121 C. The polyamides putrescine (Put), spermidine (Spd), and spermine (Spin) were filter-sterilized and added to the rooting medium at 1 mM (Rugini and Wang, 1986). Most of the experiments were carried out using diamine putrescine.

One experiment compared the effect of putrescine on rooting by exposing the explants to a 16 h-light photoperiod at 60 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ with or without basal blanching (Rugini et al., 1987). The technique consisted of maintaining the basal part of shoots in darkness during the entire period of rooting by blackening the outside of the jars up to 3 to 4 mm above the medium and by covering it with small black polycarbonate granules.

Experiments with *A. rhizogenes* (strain NCPPB 1855) were carried out using the same basal rooting medium without auxins. In addition, 5-azacytidine at 28 μM , auxins [1H-indole-3-acetic acid (IAA), indole-3-butyric acid (IBA), 1-naphthalene-acetic acid (NAA), 2,4-dichlorophenoxyacetic acid (2,4-D)], zeatin, and gibberellic acid (GA_3) at 5 μM (Table 3) were tested in an attempt to increase bacterium-induced rooting efficiency. Bat-

Abbreviations: PA, polyamides.

terial inoculation was carried out by making two superficial longitudinal cuts (5 to 7 mm long) with an infected knife on the basal portion of the explants. This procedure was compared with a bacterial inoculation by puncturing the middle of the explants with a glass needle.

The rooting tests with auxin or with *A. rhizogenes* involved 60 in vitro-grown shoots per treatment, with two to three nodes for olive and five to six for the other species. The explants were placed separately in test tubes (120 × 16 mm) containing 5 ml of medium. The cultures were then placed in a growth chamber at 24 ± 1C under 40 μmol·m⁻²·s⁻¹ light intensity, supplied by cool-white fluorescent lamps; the photoperiod was 16 h. Root growth was recorded every 7 to 10 days, according to the experiments and the species examined. At the end of the experiment, the explants were extracted from the test tube and a pH sensor was placed where the explants had been, to measure the pH of the medium. The number of roots per explant was also recorded. The roots of 15 randomly chosen explants rooted by *A. rhizogenes* were analyzed for opines by paper electrophoresis (White et al., 1982). Data were analyzed by the χ² test. Plantlets were then transferred to a mixture of 1.5 peat moss : 1.0 perlite : 0.5 polystyrene granules (by volume) in boxes covered with polyethylene film and placed under a 16-h photoperiod at 60 to 70 μmol·m⁻²·s⁻¹ in a growth room held at 20 ± 1C. Before being transferred into pots, the plantlets rooted with *A. rhizogenes* were washed for 24 h in a shaker that contained vancomycin solution at 200 mg·liter⁻¹.

Polyamine determination. Perchloric acid (PCA) and total polyamine (Put, Spd, and Spm) concentrations were determined by thin layer chromatography (TLC) (Torregiani et al., 1990) in chloroform : ethylacetate (4:2) from a 500-mg fresh weight sample. The shoots used for total PA determination were first divided into apical and basal parts, then cultured in rooting medium under the same environmental conditions as those used for the rooting test, with or without (control) basal blanching. The analyses were carried out at 2 and 5 days after the beginning of rooting, a crucial period for the root induction phase, by homogenizing duplicate samples of the whole explants.

Results

Olive. Both cultivars, Moraiolo and Dolce Agogia, gave similar rooting responses under auxin and PA treatments. PAs affected rooting only in combination with auxin treatment, increasing rooting percentage and promoting earlier root emergence compared with the explants placed on medium with auxin only; Put seemed to be a more active PA than the other two (Fig. 1). Further, Put + NAA also increased the number of roots per explant (Table 1). In auxin-free medium, with or without PAs, not more than 8% of the explants had rooted (data not shown). The aim of the experiment was to examine the effect of Put at two auxin concentrations. There was a higher percentage of rooted explants in medium containing 5 μM NAA than in medium containing 0.5 μM NAA, but when 1 mM Put was added to the media there was no difference in the final rooting percentage (Fig. 2), although the explants in the medium with lower auxin concentration rooted more slowly. At the lower auxin concentration, with or without Put, explants rooted without any basal callus formation, contrary to those placed in 5 μM NAA, which formed a large basal callus; the addition of Put promoted further growth (data not shown). When rooting was carried out with basal blanching, Put was not as effective as in the blanched explants, since this method dramatically increased the rooting percentage (Fig. 3).

Fig. 1. Effect of 1 mM polyamines [putrescine (Put), spermidine (Spd), and spermine (Spm)] on rooting of 'Moraiolo' olive explants on medium containing 5 μM NAA. Triangles indicate the difference by χ² test of homogeneity at P = 0.05 with the corresponding control mean. Put (○—○); Spd (△—△); Spm (□—□); Control (●—●). In auxin-free medium, rooting was absent or minimal. Each datum is the mean of 60 explants.

Put	51	3	4	1 a	59
NAA	33	11	12	4 b	60
NAA + Put	11	8	18	22 c	59

²Distribution between lines separated by χ² test of homogeneity, P = 0.01.

Total endogenous PAs were present at a lower concentration in shoots derived from the basal blanching method than the control at 2 days. By 5 days all PAs had decreased in concentration, and it was the same in the explants from the two rooting methods (Table 2).

At the end of the experiment, the medium containing 5 μM NAA had a pH of 4.9 ± 0.06 SD, whereas in that containing NAA and Put, the pH was significantly lower (4.4 ± 0.08 SD) around the basal portion of the explants. The variation was similar in media containing rooted and that containing unrooted explants.

Treatment with *A. rhizogenes* alone promoted rooting in 26 out of 58 treated explants. An auxin concentration of 5 μM in the medium did not increase the rooting percentage when rooting was induced by the bacteria; 2,4-D inhibited rooting and promoted a large basal callus. Zeatin and GA₃ at the same auxin concentration decreased rooting drastically (Table 3); 5-azacytidine at 28 μM delayed only the early stage of root initiation. (data not shown). Putrescine promoted early rooting and increased the final rooting percentage (Fig. 4, Table 3), as already observed in explants rooted by auxin. The roots emerged from

Fig. 2. Effect of 1 mM putrescine and NAA concentration on rooting of 'Dolce Agogia' explants. Triangles placed on each point indicate the difference by χ^2 test of homogeneity at $P = 0.05$ with the corresponding NAA concentration; at 49 days there was no difference in rooting percentage between 0.5 and 5 μM NAA in combination with putrescine. Rooting was absent without auxin. NAA at 0.5 μM (○—○), + putrescine (●—●); NAA at 5 μM (Δ—Δ), + putrescine (▲—▲); control (●—●). Each datum is the mean of 60 explants.

the basal portion of explants in most cases even when inoculation was done with a glass needle in the middle of the explant. Rooting efficiency was similar between the two inoculation methods tested.

Other species. In almond and pistachio, putrescine had no effect on rooting, in apple it had a minimal effect, since it promoted slightly earlier rooting and increased the rooting percentage when compared with shoots rooted with auxin alone (data not shown). When explants were transformed with *A. rhizogenes*, putrescine increased bacterial growth around the explants, particularly in almond and pistachio, but not in apple and olive. In all these species, as in olive, Put clearly increased basal callus formation (data not shown). Also, the roots in most cases emerged at the base of the explant, as observed in olive. In all species, only 20% of the plantlets that rooted with *A. rhizogenes* showed agropine-positive roots, including those grown in medium containing the hypomethylant drug 5-azacytidine.

Plant survival in pots was usually high, $\approx 90\%$. In some potted olive and almond plantlets, observed after 6 months in pots, the root system induced by *A. rhizogenes* clearly had more secondary roots than shoots rooted with auxins. However, the root systems were similar after 2 years in pots.

Discussion and Conclusion

The present work shows that polyamides promote early rooting and increase rooting percentage in olive explants treated with auxin or with *A. rhizogenes*. The polyamine effect, however, was partially masked by rooting the explants by basal blanching. In shoots that were rooted by this method, the total endogenous PAs were present in low concentration at 2 days. Darkness probably promoted rapid PA degradation, and the catabolic products, e.g., hydrogen peroxide, might contribute to maintaining a low concentration of IAA during the induction phase. Putrescine treatment lowered the pH of the medium around

Fig. 3. Rooting of olive with 5 μM NAA under $60 \mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ irradiance at 36 days following treatments with: L (control; rooted in 16-h photoperiod); BB (rooted with basal blanching in 16-h photoperiod); ± 1 mM putrescine (P). Note the differences in root systems and the few rooted explants in the control.

Table 2. Total endogenous PAs in apical and basal explants rooted with (+ BB) or without (- BB) basal blanching in a rooting medium containing 5 μM NAA.

Treatments	Days from beginning of experiment†	
	2	5
	<i>nmol·g⁻¹ FW ± SE</i>	
Apical - BB	139 ± 7.4	70 ± 1.4
+ BB	93 ± 2.8	72 ± 2.8
Basal - BB	157 ± 4.9	78 ± 2.1
+ BB	84 ± 0.7	79 ± 2.8

the explants, and this decrease could affect rooting. This fact makes it even more difficult to understand how PAs interfere with rooting, directly or indirectly even with their catabolic products. However, it is clear that their presence in the tissue is essential for rooting. The inhibition of polyamine synthesis by dimethylfluoronithine (DMFO) and dimethylfluoroarginine (DMFA) in *Hedera helix* L. (Geneve, 1987) and in cherry (Biondi et al., 1990) resulted in a low frequency of root primordia, supporting the hypothesis of Friedman et al. (1982) who suggested a possible regulatory role for PAs in combination with auxins in the early phase of adventitious root formation. Since Spd has been found to increase phenolic compounds in rose cell suspensions (Muhitch and Fletcher, 1986), it might contribute

Table 3. Rooting of 'Moraiolo' olive explants with *A. rhizogenes* at 70 days in combination with growth regulators (5 μ M), 5-azacytidine (28 μ M) or putrescine (1 mM).

Fig. 4. Effect of 1 mM putrescine on rooting of 'Moraiolo' olive explants induced with *A. rhizogenes* (■) and on untreated explants (□). Triangles placed on each point indicate difference by t test with the corresponding mean of the control. Each datum is the mean of 60 explants.

to the formation of the auxin-phenolic complex putatively responsible for rooting (Hess, 1962). PAs similarly affected explants treated with *A. rhizogenes* and those treated with auxins. In fact, auxin and transformation with *A. rhizogenes* may be comparable, because both increase the endogenous auxin level. Putrescine, for the most part, did not affect the presence of opine in roots induced with *A. rhizogenes* even when they grew in medium containing 5-azacytidine, which has been found to activate T-DNA genes in plants transformed by *A. tumefaciens* (van Slogteren et al., 1984). However, the agropine gene is located on the TR-DNA (De Paolis et al., 1985) and is not required for root induction, as is TL-DNA; therefore, TR-DNA may not be integrated into the DNA plant cells. In fact, the absence of agropine has already been observed even in herbaceous plants (unpublished). As far as these experiments are concerned, rooting has never taken place in the species examined without the presence of auxin, indicating that differentiation was stimulated by the *rol* genes of the bacterial plasmid TL-DNA even though the roots were agropine negative.

Because PAs promote early rooting and increase the rooting

percentage (hence eliminating the variable results often observed in our culture conditions), they could be of value even for ex vitro rooting of olive explants. Recent evidence in our laboratory showed that pretreatment of olive explants with putrescine extended their capacity for survival, and some of them rooted in agarized medium without a C source.
