Abstract. Crop evapotranspiration (ET_c) was measured as evaporative heat flux from drip-irrigated coffee (*Coffea arabica* L. cv. Yellow Catuai) fields at different stages of canopy development using the Bowen ratio-energy balance technique. Irrigation requirements were determined by comparing the ET_c values obtained against reference values (ET_0) derived from a modified Penman equation, and expressed as the ET_c/ET_0 ratio, or crop coefficient (Kc). In 1991, the average Kc was 0.75 to 0.79 for fields containing 2- to 4-year-old plantings. This ratio was 0.58 for a field containing a 1-year-old planting. Crop coefficient was 30% lower in 1992 due to higher ET_0 values and lower stomatal conductance. Measurements made between July and August and again between September and November 1991 suggested that Kc may vary seasonally. Crop transpiration (T), determined with the stem heat balance technique, comprised from 40% to 95% of ET_c as the leaf area index increased from 1.4 to 6.7. Behavior of Kc and T during a 25-day soil drying-reirrigation cycle indicated that the crop was able to maintain relatively high levels of gas-exchange activity during periods of severe water deficit.

The amount of acreage planted in coffee on Hawaii's sugar plantations has expanded dramatically during recent years. This return of coffee as a major commercial crop has been achieved through continued establishment of newly bearing acreage and improved care of the orchards. On the island of Kauai alone, over 1800 ha of coffee are being grown under drip irrigation (U.S. Dept. of Agriculture). Nevertheless, actual rates of water use by the crop have not been estimated.

Reasonably accurate water requirement estimates for coffee are crucial because too little water can substantially reduce growth without wilting or other visible signs of moisture stress (Meinzer et al., 1992). Reduced growth signifies that fewer nodes are present for flower formation and subsequent fruit production (Browning and Fisher, 1979; Cannell, 1971).

Water use by coffee and other crops is most usefully expressed as a ratio of crop evapotranspiration to the reference evapotranspiration (ET_c/ET_0), also known as the crop coefficient (Kc). Estimates of Kc for coffee grown in other regions typically range from 0.7 to 0.8 (Blore 1966; Pereira, 1957; Wallis, 1963). However, these estimates have been obtained by indirect methods such as hydrological models or assessing changes in soil moisture. Pereira (1957), using a soil-water balance model reported that Kc for coffee growing in Kenya varied seasonally from 0.5 during the dry season to 0.8 during the wet season. Wallis (1963) and later Blore (1966) used soil moisture changes to estimate the irrigation requirements of coffee in Kenya and found Kc to be 0.6 and 0.7 for nonirrigated and irrigated coffee, respectively. Validation of these estimates under local conditions is desirable because of the relatively large variation in climate and agronomic practices among

coffee growing regions.

Our objective was to assess water use by drip-irrigated coffee growing in Hawaii using more direct approaches than those previously reported for coffee growing in other regions.

Materials and Methods

Experimental site and plant material. The study was conducted in commercial coffee fields at McBryde Sugar Co., Eleele, island of Kauai (lat. 21°54'N, long. 154°33'W, elev. 98 m) from July to November in 1991 and from July to September in 1992. Precipitation patterns in Eleele are characterized by seasonal fluctuations in rainfall with a defined dry season from May to October. Large fields of *Coffea arabica* 'Yellow Catuai' from 37 to 74 ha were selected. The fields were planted in a hedgerow configuration oriented predominantly from east to west. Spacing at planting was 3.6 m between rows and 0.7 m between plants. 'Yellow Catuai' is a short and compact variety that forms dense hedgerows when cultivated at high density. Leaf area index (LAI) was 1.4, 5.3, 5.4, and 6.7 in 1991, and 3.4, 4.2, and 7.5 in 1992 in the seven fields selected. Crop age ranged from 1.2 to 5.3 years. Hedgerow dimensions increased approximately from 1.25 × 1 m at LAI = 1.4 to 3 × 2.5 m at LAI = 7.5. Average leaf area per plant (n = 8 to 10) increased from 3.68 ± 0.55 m² at LAI = 1.4 to 15.57 ± 3.26 m² at LAI = 6.7. Short seedlings of the predominant weeds, Spanish needle (*Bidens pilosa*), purple nutsedge (*Cyperus rotundus*), and several grasses grew in the interrows.

Coffee phenology in the leeward environment of Kauai is characterized by seasonality with most vegetative growth from March to November (unpublished data). Flower induction and flower bud development begin in September and October, coincident with shortening daylength, and then the flower buds undergo a dormant period extending through the dry season. Dormancy is released by the first rains (Alvim, 1960; Crisosto et al., 1992). Subsequent anthesis and fruit development start around March (unpublished data).

Environmental conditions in each field during the measurement periods (Table 1) were recorded by sensors installed on a 7-m

²Mean daily values.

instrument tower (see section on ET_c/ET_0 measurements) erected within each field. Approximately 17 to 20 mm of irrigation water were applied to each field through drip-irrigation lines placed along the base of the stems in the plant hedgerows, from 36 to 48 h before each set of ET_c determinations. The soil under the hedgerows was kept at field capacity as determined by daily monitoring of a set of 10, 20-cm long tensiometers installed in each field. This ensured that water availability was adequate over the 4- to 8-day period during which ET_c was measured in each field. In one field (LAI = 6.7), ET_c was monitored during a 25-day soil drying-reirrigation cycle.

ET_c/ET_0 measurements. Crop evapotranspiration (ET_c) was measured as evaporative heat flux using the Bowen ratio-energy balance technique (Tanner, 1960). A movable 7-m instrument tower was positioned in each field to provide an upwind fetch >100 times the crop height. The tower remained in each field for 7 to 10 days. With this method, the surface energy balance is expressed as:

$$R_n + G + H + \lambda E = 0 \quad [1]$$

Where R_n is net radiation, G is soil heat flux at the surface, H is sensible heat flux, and λE is latent (evaporative) heat flux. Net radiation was measured with a Fritschen net radiometer (model Q-6; Radiation Energy Balance Systems, Seattle) mounted 6.75 m above the soil surface. A second net radiometer was added during the second year so that each sensor was positioned directly above either the plant hedgerow or the interrow. Soil heat flux at the surface was measured using the combination method (Kimball and Jackson, 1979). One soil heat flux plate (model HFT-2; Radiation Energy Balance Systems, Seattle) and two soil thermocouples placed 1 and 2 cm below the soil surface were positioned at the edge of the hedgerow and a second soil heat flux plate and thermocouples were positioned in the middle of the interrow.

The Bowen ratio (β), the ratio of sensible to latent heat flux from the canopy, was estimated as:

$$\beta = H/\lambda E = \gamma \Delta T / \Delta e \quad [2]$$

Where γ is the psychrometric constant and ΔT and Δe are gradients of temperature and vapor pressure measured over a fixed distance in the canopy boundary layer. Combining [Eqs. 1 and 2] gives an estimate of λE as:

$$\lambda E = (R_n - G) / (1 + \beta) \quad [3]$$

The gradients of temperature and water vapor were measured with a pair of chromel-constantan thermocouples mounted 5.25 and 6.50 m above the ground using a commercially available Bowen ratio system (Campbell Scientific, Logan, Utah). Air samples were taken at the same heights and passed through a dew point hygrometer (model Dew-10; General Eastern Corporation, Watertown, Mass.), which automatically switched positions every 5 min in response to a signal from a datalogger (model CR21X; Campbell Scientific). Crop evapotranspiration (ET_c) was calculated from data averaged every 20 min.

Weather data from an automated weather station (Campbell Scientific), within 1 km of the experimental fields at McBryde Sugar Co., were used to compute daily values of reference evapotranspiration (ET_0) from a modified Penman combination equation (Doorenbos and Pruitt, 1975).

Transpiration measurements. The stem heat balance (SHB) technique (Cermák et al., 1973; Vieweg and Ziegler, 1960) as modified by Sakuratani (1981) and Baker and Van Bavel (1987) was used to estimate the transpiration rate of the coffee plants. A detailed description of the operation theory of the SHB technique has been provided elsewhere (Baker and Van Bavel, 1987; Ham and Heilman, 1990; Sakuratani, 1981). In each field, eight commercially available stem sap flow gauges (models SGB13 to SGB25; Dynamax, Houston) were installed on major branches containing 1.5 to 5.5 m² of leaf area distal to the gauge. The satisfactory performance of these gauges on coffee plants was verified by greenhouse experiments comparing SHB estimates of transpiration against weight loss of container-grown plants, and in field tests in which gauges were operated without power to their heaters to verify that externally induced stem temperature gradients were negligible (Gutiérrez et al., 1994). The sap flow gauges were operated under the control of a datalogger (model CR21X; Campbell Scientific) equipped with a 32-channel multiplexer (model AM416; Campbell Scientific). Data were recorded at 15-sec intervals and 20-min averages stored in a solid state storage module (model SM196; Campbell Scientific). At the end of each measurement period, branch leaf area was determined by complete defoliation and subsequent measurement in a leaf area meter (model 3100; LI-COR, Lincoln, Neb.). Rates of water flow through

the coffee stems were normalized by dividing by the leaf area distal to the gauge to obtain transpiration rate on a unit leaf area basis. The resulting estimate of crop transpiration was scaled to a unit ground area basis by multiplying by the corresponding value of LAI of the whole canopy (Ham et al., 1990).

Additional measurements. For determination of LAI, eight to ten representative plants in each field were defoliated at the end of the measurement period in each field, and their total leaf area was determined in an area meter (model 3100; LI-COR). Average leaf area per plant was multiplied by the plant density to obtain a LAI value for each field.

Predawn and midday leaf water potentials (ψ_L) were determined with a pressure chamber in a field with a LAI = 6.7 during a 25-day soil drying–irrigation cycle. Branch tips containing one or two pairs of fully expanded leaves were enclosed in plastic bags before excision and kept in sealed bags in darkness after excision until measurement.

Diurnal courses of stomatal conductance (g_s) were measured during 1 to 3 days in several fields with a portable photosynthesis system (model 6200; LI-COR) on sun and shade leaves in the upper and middle canopy layers.

Leaf temperature was determined with a set of 18 Cu-constantan thermocouples attached to the lower surface of the leaves and distributed throughout the canopy.

Results and Discussion

ET/ET_0 measurements. Average Kc ranged from 0.68 to 0.82 for 2- to 4-year-old crops in 1991 (Table 2). Average Kc for the 1.5-year-old field (LAI = 1.4) was 0.55. In 1992, Kc was about 0.45 for 2- to 3-year-old crops and 0.67 for the 5-year-old field. Values of Kc obtained in 1991 are consistent with those reported for coffee grown in other regions (Blore, 1966; Pereira, 1957; Wallis, 1963).

In 1991, Kc was significantly lower ($p < 0.05$) during September and November than during July and August, suggesting that a seasonal reduction in water use by coffee may have occurred independent of seasonal variation in evaporative demand. Seasonal fluctuations in stomatal activity, previously reported for coffee (Meinzer et al., 1992), may have played a role in reducing water use. These results suggest that irrigation requirements were lower during the late part of the dry season (October to December).

Crop coefficient values were substantially lower in 1992 than

in 1991 at all ages sampled (Table 2). Several factors seemed to have played a role in reducing Kc in 1992. Net radiation, a major determinant of ET_0 , was higher in 1992 (Table 1), and this was reflected in higher ET_0 values in 1992. Lower relative humidity and higher wind speed recorded during 1992 (Table 1) may also have contributed to the observed reductions in ET_c (Table 2) by reducing stomatal conductance. Coffee stomata have previously been reported to exhibit a strong closing response to reduced atmospheric humidity (Fanjul et al., 1985). Average stomatal conductance (g_s) was 0.10, 0.11, 0.12, and 0.07 $\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ in fields with LAI = 6.7, 5.3, 5.4, and 1.4, respectively, in 1991, whereas in 1992 average g_s was 0.08, 0.11, and 0.05 $\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ in fields with LAI = 7.5, 4.2, and 3.4 (Table 2). Higher Bowen ratios were also recorded in 1992 (0.60 to 0.92) than in 1991 (0.45 to 0.66), indicating that a larger proportion of net radiation was consumed as sensible heat in 1992, although the irrigation regimes were similar both years.

The increase in ET_c with LAI during each season reflected the activity of a larger evaporating surface as the canopy developed. Changes in the $\lambda E/R_n$ ratio as a function of LAI appeared to follow a sigmoidal pattern, increasing from 0.4 at LAI = 1.4 to values close to 0.6 at high LAI (data not shown). At LAI = 6.7, the canopy shaded the soil during most of the day, suggesting that the remaining net radiation was consumed mainly as sensible heat, and that further increments in ET_c with increasing LAI may have been small.

Transpiration. The transpiration component (T) of ET_c , expressed as the ratio T/ET_c at different values of LAI (Fig. 1), followed a pattern consistent with previous observations on several annual crops (Al-Kaisi et al., 1989; Brun et al., 1972; Ritchie and Burnett, 1971). These reports mention the existence of a threshold LAI at which T equals ET_c . Threshold LAI has been found to be nearly 4 for soybean and sorghum (Brun et al., 1972), 2.7 for sorghum and cotton (Ritchie and Burnett, 1971), and from 3 to 3.7 for maize (Al-Kaisi et al., 1989). For coffee fields grown under wide row spacing in a hedgerow configuration, T comprised 30% to 40% of ET_c at low LAI values, and then increased steadily to 95% at LAI = 6.7 (Fig. 1).

Diurnal patterns of T and ET_c for different LAI values (Fig. 2) confirmed that at low LAI (1.4 and 3.4) T comprised a small fraction of ET_c (see also Table 2), while at high LAI (6.7), T tended to equal ET_c except during midday hours, when soil evaporation

²Data not available.

Fig. 1. The relationship between crop transpiration expressed as a fraction of crop evapotranspiration (T/ET_c) and canopy development (leaf area index) in coffee fields.

presumably became more important as a result of increasing irradiance in the interrows. Coffee transpiration rate measured with the SHB technique closely agreed with average values of 0.8 to 0.9 $\text{mmol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ previously determined by Nutman (1941) using a lysimeter. Substantial evaporation of dew from the canopy surface seemed to have occurred on 30 Aug. 1991, as judged by the high ET_c recorded in the absence of T during the early morning hours (Fig. 2).

These diurnal courses revealed that in fields with low LAI values (1.4 and 3.4) ET_c was higher between 1400 and 1600 h than earlier in the day (Fig. 2). This contrasts with T , which peaked during the morning and early afternoon hours in fields with low LAI. At LAI = 6.7, both ET_c and T reached maximum rates around midday and decreased steadily during the afternoon. The behavior of ET_c in fields with low LAI did not appear to be associated with R_n , which began to decrease at ≈ 1400 h (Fig. 2). Soil temperature, on the other hand, attained its maximum values at about 1400 h in fields with low LAI and may have caused ET_c to remain high during the latter part of the day (Fig. 2). In fields with high LAI (6.7, Fig. 2) where T/ET_c was close to 1, soil temperature was lower and decreased rapidly after midday. Fields with low LAI thus reduced interception of radiation by the coffee canopy and increased the amount of radiation available for heating of the soil surface.

Patterns of leaf temperature in relation to soil temperature also suggested that soil heating played an important role as a driving force for evapotranspiration in fields with low LAI by increasing soil water evaporation and/or understory transpiration. In the field with the lowest LAI (1.4, Fig. 2), leaf temperature was at least 4°C lower than soil temperature during the afternoon hours. In fields with higher LAI, the daily course of leaf temperature closely paralleled that of soil temperature, particularly in the afternoon hours. The behavior of soil and leaf temperature and of ET_c and T in relation to LAI suggests that it may be possible to reduce water consumption in coffee fields with low LAI by removing the vegetation growing in the interrows or by the use of organic or plastic mulches. However, such practices may also increase soil surface temperature (e.g., in dry soil) and promote within-row

Fig. 2. Diurnal courses of net radiation, crop transpiration (T), and evapotranspiration (ET_c) determined with the SHB and Bowen ratio techniques, respectively, and leaf and soil temperature at three different leaf area indexes.

Fig. 3. Changes in the crop coefficient (K_c) (A), crop and interrow latent heat flux to net radiation ratio (B), and crop transpiration to crop evapotranspiration ratio (C), in a 4-year-old coffee field (leaf area index = 6.7) monitored during a soil drying-reirrigation cycle between 29 Aug. and 23 Sept. 1991.

advection, increasing crop transpiration and keeping the net flux of water from the field unchanged (Villalobos and Fereres, 1990).

Responses to water deficit. A 25-day soil drying-reirrigation cycle was imposed on a field with LAI = 6.7. K_c began to decline shortly after irrigation was suspended (Fig. 3A). After day-to-day variations in T and ET_c were normalized by dividing by the corresponding daily R_n , it became apparent that the initial decline in K_c was entirely attributable to reductions in T after irrigation was discontinued (Fig. 3B). After 8 days without irrigation, T/ET_c began to decline also, indicating that the soil and the interrow vegetation began contributing to ET_c (Fig. 3C). Examination of the components of ET_c revealed that the decline in $\lambda T/R_n$ (Fig. 3B) was continuous, but 8 days after withholding irrigation the interrows began contributing to ET_c . Leaf wilting presumably played a role in causing this response by increasing the ground area exposed to direct radiation.

Transpiration (normalized for variations in R_n) started to decline (Fig. 3B) before any reduction in ψ_L could be detected (Fig. 4). This indicated that stomatal restriction of transpiration was taking place in the absence of changes in the bulk leaf water status. Observations consistent with this behavior have been interpreted as cases of root-to-shoot communication (Bates and Hall, 1981; Crisosto et al., 1992; Davies and Zhang, 1991), in which root signals mediate stomatal responses to soil drying before changes in the water status of the shoot occur.

Fig. 4. Changes in predawn and midday leaf water potential (ψ_L) during a soil drying-reirrigation cycle in a field with a leaf area index = 6.7, between 29 Aug. and 23 Sept. 1991.

Crop coefficient had dropped to about 0.4 when irrigation was resumed 18 days after the last irrigation. Although the leaves were visibly wilted by this time and ψ_L had reached -2.14 MPa at midday (Fig. 4), the K_c value of 0.4 and the value of T at $\approx 30\%$ of its original value suggested that substantial gas exchange was still taking place. Stomatal conductance decreased from $0.10 \text{ mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ under well-irrigated conditions to $0.02 \text{ mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ 23 days after the drying cycle had been imposed. Upon reirrigation, ψ_L , T , and K_c rapidly returned to their original levels. These observations are consistent with previous reports that coffee is able to sustain relatively high levels of gas-exchange activity even under severe water deficit (Meinzer et al., 1990), and they attest to coffee's high degree of drought tolerance.

Conclusions. Given the important role played by water deficit in the control of flower opening in coffee (Alvim, 1960), the data obtained in the present study should prove useful in the formulation of models aimed at manipulating the water regime to control coffee flowering under field conditions (Crisosto et al., 1992). Our results indicate that K_c for coffee ranged from 0.7 to 0.8 at all except the lowest values of LAI examined, and that the crop maintains a substantial level of gas exchange even under severe water deficits. Crop transpiration became an increasingly important component of ET_c as the canopy developed, and soil temperature (i.e., within-row advection) played a predominant role in driving evapotranspiration at early stages of canopy development. Variations in stomatal behavior seemed to be responsible for seasonal and year-to-year differences in water use and K_c .
