Abstract. Dynamics and distribution of K, Ca, Mg, P, and Na were studied in leaves of three cultivars of habanero pepper (Capsicum chinense Jacq.) at the time of transplanting and 8 and 14 weeks afterward. Most nutrients analyzed were mobilized from younger to mature leaves, except for P, which occurred in the opposite direction, probably due to its role in the synthesis of nucleic acids, which is more active in young tissues. Information about mineral distribution in leaves during the first 14 weeks after transplantation could be used to indicate plant nutritional status and fertilizer requirements.

Materials and Methods

Plant materials and conditions. Three-week-old habanero pepper plants of the local variety of orange fruit were obtained in Chichxulub, Yucatán, México (latitude 21°0.1 N longitude 89°34 W). Plants were germinated from seeds in Pet Moss (Cosmo Peat, Cosmocell distributor) until they reached 12 to 15 cm in height and presented five pair of leaves before being transplanted to plastic bags containing 500 g of a mixture of 2 red soil (luvisol) : 1 sand (by volume). Three sets of plants were organized. The first one consisted of five individual plants harvested 3 weeks after germination, before transplanting, whereas the second and third sets (of five plants each) were allowed to develop for 8 and 14 weeks, respectively.

Sample harvest and processing. In each sampling, all leaves of each plant were harvested, sorted out by size, and wrapped in aluminum foil. Leaves were numbered, starting with the youngest one. Leaves were weighed and dried individually in an oven to a constant weight at 60 °C for 48 h. Porcelain crucibles containing leaf samples were placed in a oven, muffle furnace type, at 200 °C for 1 h and then at 500 °C for 2 h. The ashes obtained were digested with 5 mL of 40% HCl and the slurry was evaporated to dryness on a hot plate. The residue was dissolved in 1 mL of concentrated HCl and placed in test tubes, where 9 mL of distilled water was added.

Determination of Ca, Mg, K, and Na. These determinations were performed using a atomic absorption spectrophotometer (model 3100; Perkin Elmer) operated at wavelengths of 400 to 766 nm with a detection range of 0 to 5.0 mg·L–1, depending on the analyzed ion, according to Greenberg et al. (1992). PE Pure atomic spectrophotometer standards were used in the measure of the nutrients.

Determination of P. Phosphorus was colorimetrically analyzed with ascorbic acid as described by Murphy and Riley (1962). Readings of the blue complex formed were taken on a spectrophotometer (DU 65; Beckman) at 880 nm, with a detection range of 0.04 mg·L–1.

Statistic analysis. Data were submitted to analysis of variance and Tukey’s multiple media test (p ≤ 0.05) using the StatGraphics v. 5.1 package. All data were recorded as the average of three independent experiments.

Results and Discussion

Habanero pepper plants that were 3 weeks old at the time of transplantation were cultivated in a mix of 2 soil : 1 sand with the following concentrations of mineral nutrients (all dry weight): K = 0.002275 ± 0.00052 g·kg–1, Ca = 0.2062 ± 0.0054 g·kg–1, Mg = 0.01246 ± 0.00079 g·kg–1, Na = 0.014 ± 0.00084 g·kg–1, and P = 2.83 × 10–3 ± 10–4 g·kg–1.

These plants, for which the mineral contents are shown in Table 1, had been maintained inside the greenhouse and were in good physiological conditions with five pairs of leaves. Figure 1 shows the concentration of the studied ions, expressed in g·kg–1 of dry weight. In 3-week-old plants, the concentrations of K, Ca, and Mg ions increased from the younger, upper leaves to the older ones, located in the lower part of the plant. The concentration of Na ions was lower in the younger leaves, and the highest concentration was found in the older leaves.

Table 1. Concentration of the different elements studied in the youngest (top pair of leaves) and the oldest (bottom pair of leaves) leaves given in g·kg–1 (dry weight).1

stem positions. This trend was similar in 8- and 14-week-old plants (Fig. 1A–C). Differences in ion concentrations were more pronounced among the top and bottom pairs of leaves in 3-week-old plants than in the older ones. This was more evident for K and Mg than for Ca (Fig. 1A and C).

To compensate the effect of leaf expansion and biomass accumulation, data were recalculated as total ion content per leaf (Fig. 2), both for K (33.84 to 55.03 g·kg⁻¹) and Mg (48.46 to 148.37 g·kg⁻¹) (Fig. 2B and C, Table 1).

The mobilization of these ions is an expected response, since the plant accumulates Mg through the synthesis of chlorophylls. In the case of K, the mobilization is directly related to the functionality of the stoma as well as of the other multiple functions with which K is involved. Similar results have been reported for *Phoenix canariensis* (Broschat, 1997).

In habanero pepper there do not exist any reports, not even about the role of K fertility as it affects pepper plant growth yield and pungency. There are two reports on *Capsicum annuum* L. and the relationship of the effects of the mineral supplementation on fruit development and pungency. Biomass, fruit count, and fruit weight per plant increased linearly with increasing K rate (Johnson and Decoteau, 1996). Fertilization regime may alter the balance of the competition between capsai­doid biosynthesis and accumulation of lignin-like substances in the cell wall (Estrada, et al., 1998), but nothing has been reported in relation to measure of the nutritional conditions of chilli pepper plants.

For plants belonging to the *Solanaceae* family, Na is not an essential nutrient and it could even be the cause of damage (Adams et al., 1995). The concentration of Na decreased in the leaves of plants harvested at 3 weeks but increased slowly in the leaves of plants harvested at 8 and 13 weeks. Blom Zandstra et al. (1998) reported that, in sweet pepper (*C. annuum*), pith cells, the intermediates between the xylem and phloem, play a decisive role in the recirculation of Na throughout the plant. This study was done under hydroponic conditions and found that sweet pepper possesses the same characteristics for well-controlled recirculation of Na as described for bean (Jacoby, 1979).

The mobilization of nutrients from young to well developed leaves has been reported for conifers, in which it was noticed that mobilization is independent of leaf senescence (Escudero et al., 1992; Nambiar and Fife, 1987). For Na and P (Fig. 1D and E), youngest leaves had greater quantities of these ions, and significant differences were found between the first and the last leaves (Table 1); thus, we conclude that the mobilization of these two elements is carried out from the oldest to the youngest leaves.

The tendency observed, as in the case of the other two ions described previously, is that the ions are mobilized from the oldest to the youngest. Although we need to highlight that the detected quantities were low, which could be due to the direct involvement of Na in maintaining the osmotic potential of growing leaves. The concentration of Ca increases consistently as the leaf ages (Fig. 1B, Table 1). The totally expanded young leaves could be a good indicator of the status of Ca in this species.

Prevot and Monbreton (1958) have shown a similar increment in the concentration of Ca along with leaf senescence in African palms, but Amalu et al. (1988) have reported a slight decrease in Ca concentration in *Nigerian Tall* coconut palms while the plants age.

In all the cases (Fig. 1A–D), except for P (Fig. 1E), during the second and third harvests (8 and 14 weeks after transplantation), the tendency of the ions studied is to be mobilized from the youngest to the oldest leaves with the purpose of being eliminated, since in high concentrations these ions are toxic. In the purpose of being eliminated, since in high concentrations these ions are toxic. In the case of K, the tendency was to keep its mobilization from the oldest to the youngest leaves (Table 1), due to its role in the synthesis of nucleic acids as well as the part it plays in transferring energy needed for the phosphorylation of proteins used for cell growth and cellular differentiation (Budded and Chollet, 1988).

Figure 2 represents the total quantity of the different nutrients present in the leaves of habanero pepper plants. The tendency of the three crops is the same: there was an increase of the nutrient quantities in leaf four (Fig. 2A–E), which is indicated by the increment of leaf growth, which occurs along with a total increment of the studied nutrients. It was noticed that the quantities of the nutrients began to diminish from leaf five to the last one in all the crops studied, indicating that there is a mobilization of nutrients toward the intermediate leaves.

---

**Fig. 1.** Concentration of K (A), Ca (B), Mg (C), Na (D), and P (E), as g·kg⁻¹ dry weight (DW), in leaves of *Capsicum chinense* plants 3 (▲), 8 (◆), or 13 (▲) weeks old. Leaf in position 1 represents the youngest fully expanded pair of leaves, located in the upper stem. Average of three independent repetitions.

**Fig. 2.** Total content of K (A), Ca (B), Mg (C), Na (D), and P (E), in leaves of *Capsicum chinense* plants 3 (▲), 8 (◆), or 13 (▲) weeks old. Leaf in position 1 represents the youngest fully expanded pair of leaves, located in the upper stem. Average of three independent repetitions.
these are the leaves with highest metabolism that require all these nutrients for adequate development. Although the youngest leaves continue gaining fresh weight, the quantity or the accumulation of these nutrients does not vary due to the mobilization phenomenon. Similar results have been observed in senescent leaves of 89 species of deciduous and evergreen woody perennials (Killingbeck, 1996).

Conclusions

Never before have chilli pepper plants been studied in relation to their nutritional conditions. Only the role of N, P, and K fertility on Jalapeño and Padrón pepper plant growth, yield, and pungency have been reported. This is the first report on the dynamics and distribution of nutrients in plants of habanero pepper. The nutrients studied seem to be highly mobile in the leaves of habanero pepper plants. The mobility of Ca, K, and Mg increases with leaf age, while that of P decreases. In the case of Na, no difference was observed in the leaves studied, suggesting that habanero pepper plants do not accumulate this element. The studies carried out in this work can serve as a measure of the nutritional conditions of habanero pepper plants.
