Effects of Drying and Extraction Conditions on the Biochemical Activity of Selected Herbs

Weiguang Yi and Hazel Y. Wetzstein
Department of Horticulture, 1111 Plant Science Building, The University of Georgia, Athens, GA 30602-7273

Abstract. Herbs have been long known to provide health-promoting benefits and are demonstrated to have antioxidant, anti-inflammatory, antibacterial, analgesic, and antitumor activities. This study evaluated the effects of drying conditions and extraction protocols on the biochemical activity of three culinary and medicinal herbs: rosemary (Rosmarinus officinalis), motherwort (Leonurus cardiaca), and peppermint (Mentha piperita). Leaf tissues were dried by sun, oven-dried at 40 °C, or oven-dried at 70 °C and extracted using 80% methanol or 80% ethanol. Total polyphenol (TPP) using the Folin-Ciocalteu reagent method and antioxidant capacity using the Trolox-equivalent antioxidant capacity (TEAC) assay were determined. Both drying and extraction conditions significantly impacted TPP content and TEAC capacity than fresh samples, suggesting low-temperature drying may be a good postharvest means to store medicinal/culinary herbs. Exposure to 70 °C oven-drying caused significant antioxidant loss. In addition, the current study showed that with fresh tissue, 80% ethanol extraction had significantly higher TPP and TEAC than 80% methanol extraction for all three herbs, yet for dried herbs, the efficacy of ethanol/methanol extraction varied with different drying treatments.

Herbs and spices have been used not only as food preservatives and flavoring, but also as traditional medicines for thousands of years. Two-thirds of the world's population still relies on traditional medicines with herbal medicines the most common form. The World Health Organization (2010) estimates that 80% of the population in some Asian and African countries depends on traditional medicines for primary health care. In the United States, the Centers for Disease Control and Prevention estimates 38% of adults use complementary and alternative medical treatments. Scientific evidence increasingly supports the potential health benefits of herbs with plant extracts displaying antioxidant, anti-inflammatory, antibacterial, analgesic, and antitumor activities.

Oxygen-free radical induced oxidation of cellular components is believed to be one of the major factors in the development of heart disease and cancer (Berger, 2005). Oxidizing agents, often in the form of free radical compounds, can cause damage to numerous cellular components, including membranes, proteins, and nucleic acids (Knight, 2000). Dietary intake of herbs and spices with high antioxidant contents may improve our resistance to free radical damage and thus reduce risk of heart disease and cancer (Kaefer and Milner, 2008). Studies show that herbs generally contain higher levels of antioxidant content than fruits, vegetables, and nuts (Konczak et al., 2010; Zheng and Wang, 2001). More and more people have realized the health benefits of herbs and the use of herbs is increasing (Kaefer and Milner, 2008).

The drying of spices has been used for disinfections, microbial decontamination, and long-term preservation (Schweiggert et al., 2007). Although reports are limited, studies indicate that drying conditions can impact the chemical and biological activities of herbs (Capecka et al., 2005; Lim and Murtiayana, 2007). The Mint family, Lamiaceae, is a group of 210 genera and some 3500 species. Many members of the family have high phenolic and antioxidant content such as basil (Ocimum basilicum), lemon balm (Melissa officinalis), sweet marjoram (Origani majorana), oregano (Origanum vulgare), peppermint, rosemary, sage (Salvia officinalis), and thyme (Thymus vulgaris) (Dragland et al., 2003; Yi and Wetzstein, 2010). Systematic evaluations of drying and extraction conditions on biochemical activities of this group are lacking. The objectives of this study were to evaluate the effects of drying conditions and extraction protocols on total phenolic content and antioxidant capacity of selected herbs.

Materials and Methods

Plant materials, harvesting, and drying. Three herbs, rosemary (Rosmarinus officinalis), motherwort (Leonurus cardiaca), and peppermint (Mentha piperita), were grown in a greenhouse at the University of Georgia, Athens, GA, from Feb. 2009 to Apr. 2009. Herbs were planted in 30-cm wide pots with Fafard 3B soil and grown under natural light conditions at 21 ± 2 °C. The plant heights at harvest were: peppermint, 35 to 40 cm; motherwort, 45 to 55 cm; and rosemary, 40 to 45 cm. For all species, tissue samples were collected from the apical portion of branches and consisted of the youngest, fully expanded leaves. None of the plants were flowering. Average leaf sizes were: peppermint, 1.7 cm wide × 2.7 cm long; motherwort (collected without petioles), 7.0 cm wide × 7.2 cm long; and rosemary, 0.34 cm wide × 3.2 cm long.

Freshly harvested leaf tissue was subjected to one of three drying methods: 1) sun-dried in the greenhouse; 2) oven-dried at 40 °C in a forced-air oven; or 3) oven-dried at 70 °C in a forced-air oven. Tissues were dried for 4 d. The moisture content of the tissues was calculated using a subset of tissues dried under 70 °C in a ventilation oven. Fresh samples served as a control.

Extraction. Extraction procedures followed a previous report of Yi and Wetzstein (2010). Fresh leaf samples, sun-dried samples, 40 °C oven-dried, or 70 °C oven-dried samples (each replication was on 3 g of a fresh weight basis) were homogenized with a frozen mortar and pestle. Fresh samples were mixed with 50, 100, 200, 300, and 400 mg GAE (gallic acid equivalent) per gram of fresh weight or 80% methanol with agitation on an orbital shaker for 2 h at room temperature under darkness in 50 mL of 80% methanol or 80% ethanol with agitation on an orbital shaker at 200 rpm. The crude extract solutions were centrifuged at 8000 g for 15 min and supernatants were collected. Samples were re-extracted for 1 h in the same solvent for two more times. The extracts were combined and then further passed through 0.2-μm nylon filters.

Total polyphenol measurement. TPP was measured according to the Folin-Ciocalteu reagent method (Singleton and Rossi, 1965). Sample solutions were mixed with Folin-Ciocalteu reagent and 7.5% sodium carbonate (w/v) and allowed to stand for 30 min. Absorption at 765 nm was measured using a spectrophotometer (Spectronic 21D; Milton Roy, Rochester, NY). The total polyphenolic content was expressed as milligrams of gallic acid equivalent per gram of dry extract (GAE mg g⁻¹) using a standard curve generated with 50, 100, 200, 300, and 400 mg mL⁻¹ of gallic acid.

Antioxidant capacity measurement. The antioxidant capacity was measured following a slight modification of the method reported by Re et al. (1999). In the modified procedure, 30 μL of extract was added to 2970 μL of
ABTS (Yi and Wetzstein, 2010). For calibration, Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid, a vitamin E analog) standards of 0, 300, 600, 900, 1200, and 1500 μM were used. The TEAC of the sample was calculated based on the inhibition exerted by the standard Trolox solution at 6 min. Absorption at 734 nm was measured using a spectrophotometer (Spectronic 21D; Milton Roy). TEAC antioxidant capacity was expressed as TE μM g⁻¹, which stands for micromolar of Trolox equivalent per gram of dry extract.

Statistical analysis. Statistical analysis was conducted using the General Linear Model (SAS 9.1; SAS Inst., Inc., Cary, NC). The TPP content, TEAC antioxidant capacity of three selected herbs under different drying, and extraction conditions were assessed by Student's t test and compared by Duncan’s multiple range test at α = 0.05.

Results

The TPP content and TEAC antioxidant capacity of rosemary under different extraction and processing conditions are shown in Figure 1A–B. Among the four different drying conditions, the highest TPP value was observed with sun-dried leaves. The TPP was 39.6 GAE mg g⁻¹ when extraction was conducted using methanol, and 34.3 GAE mg g⁻¹ when extraction was conducted using ethanol. With methanol extraction, fresh, and oven-drying at 40 or 70 °C resulted in similar TPP values; with ethanol extraction, oven-drying at 40 and 70 °C resulted in the lowest TPP values. TPP was significantly highest with sun-drying, even beyond that in fresh tissue. Oven-drying at either temperature resulted in TPP concentrations similar to fresh tissues when extracted with methanol or significantly lower than fresh or sun-dried tissues with ethanol extraction.

Similar results were obtained in TEAC antioxidant capacity of rosemary (Fig. 1B). For the methanol extraction, the highest TEAC value (TE 291.8 μM g⁻¹) was observed with sun-drying; fresh, oven-drying at 40 or 70 °C resulted in significantly lower TEAC values than sun-drying. With ethanol extraction, fresh and sun-drying showed significantly higher TEAC values than oven-drying at 40 and 70 °C. The type of solvent used during extraction had a significant effect in fresh and sun-dried samples but not in oven-dried tissues. With fresh tissue, significantly higher TPP and TEAC were obtained with ethanol versus methanol extractions. In contrast, with sun-dried samples, higher TPP and TEAC values were obtained using methanol versus ethanol.

In contrast to rosemary, motherwort consistently had the highest TPP and TEAC values with tissues that were dried at 40 °C (Fig. 2A–B). When Leonurus leaves were extracted using methanol, 40 °C oven drying resulted in the highest TPP (GAE 38.1 mg g⁻¹) compared with fresh samples, which showed the lowest TPP at GAE 17.5 mg g⁻¹. Likewise, when extraction was conducted using ethanol, the highest TPP was observed with 40 °C oven-dried samples. Successively lower values were obtained in sun-dried, 70 °C oven-dried, and fresh tissues. With ethanol extraction, TPP in sun-dried and 40 °C dried tissues were similar and significantly higher that fresh and 70 °C dried samples. The highest TEAC value (TE 366.8 μM g⁻¹) was obtained with methanol extraction in tissues dried at 40 °C. Similar to what was observed in motherwort, successfully lower values were obtained in sun-dried, 70 °C oven-dried, and fresh tissues. With ethanol extractions, TPP in sun-dried and 40 °C dried tissues were similar and significantly higher that fresh and 70 °C dried samples. The highest TEAC value (TE 382.5 μM g⁻¹) was observed with sun-dried tissues followed by 40 °C, 70 °C, and fresh samples. The effect of solvent extraction on TPP and TEAC values depended on the method of drying. In both TPP and TEAC, ethanol resulted in significantly higher values in fresh and sun-dried tissues than methanol. However, ethanol was less effective than methanol if tissue was dried at 40 °C.

The ranking order of TEAC values of peppermint leaves under different processing conditions are shown in Figure 3A–B. In general, the highest TPP and TEAC values were observed in tissues that were either sun-dried or oven-dried at 40 °C. Highest TPP (GAE 86.0 mg g⁻¹) and TEAC (TE 366.8 μM g⁻¹) values were obtained with methanol extraction in tissues dried at 40 °C. Similar to what was observed in motherwort, successively lower values were obtained in sun-dried, 70 °C oven-dried, and fresh tissues. With ethanol extractions, TPP in sun-dried and 40 °C dried tissues were similar and significantly higher that fresh and 70 °C dried samples. The highest TEAC value (TE 382.5 μM g⁻¹) was observed with sun-dried tissues followed by 40 °C, 70 °C, and fresh samples. The effect of solvent extraction on TPP and TEAC values depended on the method of drying. In both TPP and TEAC, ethanol resulted in significantly higher values in fresh and sun-dried tissues than methanol. However, ethanol was less effective than methanol if tissue was dried at 40 °C.

The ranking order of TEAC values of peppermint leaves under different postharvest treatments varied with the solvent. When the extraction was conducted using methanol, 40 °C oven-dried samples showed the highest TEAC value followed by sun-drying, 70 °C oven-drying, and then fresh samples. Meanwhile, when the extraction was conducted using ethanol, sun-dried samples showed the highest TEAC value (TE 63.8 μM g⁻¹) followed by oven-drying at 40 °C, 70 °C, and then fresh samples. When comparing different solvents, ethanol gave significantly higher TPP and TEAC in fresh and sun-dried peppermint leaves than methanol, although methanol resulted in higher TPP and TEAC in 40 °C oven-dried samples.

Discussion

Heat processing can have detrimental effects on natural antioxidants in raw plant
Drying of sea buckthorn (*Hippophae rhamnoides*) leaves at temperatures ranging from 50 to 100 °C resulted in decreased concentrations of TPP with greater reductions observed with higher temperatures and longer times (Guan et al., 2005). In the herb, *Phyllanthus amarus*, oven- or microwave-drying treatments led to significant reductions in antioxidant property with microwave-drying causing the highest decrease in total polyphenols, radical scavenging activity, and ferric-reducing antioxidant power antioxidant capacity (Lim and Murtijaya, 2007). Intense and/or prolonged thermal treatment can cause significant loss as a result of the heat instability of compounds (Tomaino et al., 2005). In the current study, the significant loss of TPP and TEAC at 70 °C compared with sun- or 40 °C oven-drying was likely the result of the breakdown of phenolic compounds under high heat conditions.

In contrast to high temperature, the current study showed drying at low temperature can increase total polyphenol contents and antioxidant capacity. Sun-drying and 40 °C oven-drying resulted in significantly higher TPP and TEAC than fresh samples of peppermint and motherwort. It is not uncommon that drying can increase TPP and antioxidant capacity. Oboh and Akindahunsi (2004) reported that sun-drying caused a significant increase in TPP, reducing property, and free radical scavenging ability of green leafy vegetables, although it can cause significant loss of vitamin C. Capecka et al. (2005) reported that air-drying of oregano and peppermint at 25 to 32 °C resulted in significant increases in TPP. This agrees with our current study, which generally showed sun and 40 °C oven-drying resulted in significant increases to TPP and TEAC in herbs.

The increase of phenolic contents and antioxidant capacity may be the result of the formation of novel compounds with antioxidant activity. Tomaino et al. (2005) suggest that the increase of safrole, myristicin, and other secondary compounds could be associated with increased free radical scavenging activity as a result of heating in nutmeg (*Myristica fragrans*). Similar bioconversion phenomena were reported in *Artemisia annua* leaves (Ferreira and Luthria, 2010). Increase in artemisinin content in sun-dried leaves was attributed to improved bioconversion from dihydroartemisinic acid (a precursor of artemisinin) to artemisinin.

Another explanation for the enhanced effects associated with drying is inactivation of deteriorative enzymes such as lipoxigenase and polyphenol oxidases (PPO). PPO, mixtures of monophenol oxidase and catechol oxidase enzymes, are widely present in herbal tissues and can oxidize diphenols in the presence of O2 molecules, causing rapid enzymatic oxidation of natural antioxidants. PPO are reported to be completely inactivated by heating at 80 °C for 10 min (Schweiggert et al., 2007). Lim and Murtijaya (2007) suggested that inactivation of PPO may be a reason why dried herbs can have higher TPP and TEAC value than fresh samples.

Cooking of herbs enhances antioxidant activity as a result of the liberation of higher amounts of antioxidants (such as bonded phenolic compounds) resulting from thermal destruction of cell walls and subcellular compartments (Jimenez-Monreal et al., 2009).
Similarly, cell wall and membrane degradation may be associated with drying and may play an important role in drying-increased TPP and TEAC. In the present study, postharvest drying of herbs enhanced TPP and TEAC in all three herb species with optimal levels obtained with sun- or 40 °C oven-drying. Regardless of whether bioconversion, enzyme inactivation, or loss of cell wall compartmentalization are the causes, drying can enhance the yield of TPP and TEAC. The dietary intake of sun-dried or low-temperature dried herbs and spices may help increase the bioavailability and absorption of these phytochemical antioxidants. Further studies are underway in our laboratory to evaluate the effects of drying on the bioavailability and bioactivity of these herbs.

For the three herbs evaluated in the current study, high TPP was generally associated with high TEAC. This is in general agreement with previous reports, which often show a linear relationship between TPP and antioxidant capacities. This may be attributed to phenolic compounds having a major contribution to the antioxidant capacity of herbs (Zheng and Wang, 2001).

Solvent extraction of phenolic compounds is widely used in herbs and spices. A number of organic solvents have been used, including water, ethanol, methanol, acetone, and ethyl acetate at different mixture ratios (Areias et al., 2000; Durling et al., 2007). The efficacy of different solvents varies with species and compounds of interest. Lim and Murtijaya (2007) compared methanol and water extracts in freeze-dried sage and found that methanol produced significantly higher phenolic content than water. To extract flavonoids and phenolic acids, Areias et al. (2000) compared in sage the efficacy of petroleum ether, chloroform, ethyl ether, ethyl acetate, acetone, methanol, 30% ethanol, 80% ethanol, and boiling water. They found that ethyl ether, ethyl acetate, and acetone were the most efficient for extraction. Areias et al. (2001) also evaluated extraction solvents in fresh peppermint. Comparing petroleum ether, chloroform, ethyl ether, ethyl acetate, acetone, and methanol, they found that ethyl acetone showed the highest efficacy, generating the greatest number of phenolic compounds. The efficacy of ethanol in extraction of fresh herbs is further supported by the results of our current study in which two of the most widely used solvents, methanol and ethanol, were compared. Here we showed that for fresh herbs, ethanol extraction had significantly higher polyphenol contents and TEAC antioxidant capacity, yet for dried herbs, the efficacy of ethanol/methanol extraction varied with different drying treatment. The effectiveness of different solvents varied not only with species and compounds of interest, but with sample drying conditions. Furthermore, solvent choice should include not only yield, but also environmental considerations. Ethanol extraction may be more desirable in some cases because it is less toxic and more environmentally friendly than methanol.

In conclusion, both drying and extraction conditions can significantly impact TPP and antioxidant capacity of peppermint, rosemary, and motherwort leaves. Sun-dried or 40 °C oven-dried herbs exhibited significantly higher TPP and antioxidant capacity than fresh samples, suggesting low-temperature drying may not only be a good post-harvest means to store medicinal/culinary herbs, but provides improved biochemical activity. Exposure to 70 °C oven-drying caused significant antioxidant loss compared with low-temperature drying. Furthermore, the current study showed that with fresh tissue, ethanol extraction had significantly higher polyphenol contents and TEAC antioxidant capacity than methanol extraction for all three herbs evaluated. Yet for dried herbs, the efficacy of ethanol/methanol extraction varied with different drying treatment, indicating that the efficacy of different solvent extraction varied not only with species and compounds of interest, but with different sample drying conditions as well.
